Clinical-nutritional, inflammatory and oxidative stress predictors in hemodialysis mortality: a review

Predictores clínico-nutricionales, inflamatorios y de estrés oxidativo en la mortalidad por hemodiálisis: una revisión

Abstract

The evaluation of clinical-nutrition status is essential to increase life quality and improve clinical outcomes of patients in hemodialysis (HD). In the absence of a gold standard, the goal of this integrative review was to present and discuss the latest scientific literature on the ability of clinical-nutritional indicators and inflammatory and oxidative stress markers to predict morbidity and mortality in HD. In this context, the lean and fat mass indexes have become good predictors of mortality in HD individuals, regardless of BMI. Subjective scoring systems have been more sensitive to malnutrition, and altogether anthropometric indicators may result in an early detection of mortality risk in this population. On the other hand, inflammation in HD, as assessed by C-reactive protein, is not only related to cardiometabolic alterations, but it is also one of the key-points in the development of malnutrition, exacerbated by the state of oxidative stress, which has been identified in this group by the increase of the serum levels of gamma-glutamyl transferase and malondialdehyde.

Resumen

La evaluación del estado clínico-nutricional es esencial para aumentar la calidad de vida y mejorar los resultados clínicos de los pacientes en hemodiálisis (HD). En ausencia de un patrón oro, el objetivo de esta revisión integrativa fue presentar y discutir la literatura científica más reciente sobre la capacidad de indicadores clínico-nutricionales, y marcadores de estrés oxidativo e inflamatorio, en la predicción de mortalidad y mortalidad en HD. En este contexto, los indices de masa grasa y grasa se han convertido en buenos predictores de mortalidad en individuos con HD, independientemente del IMC. Los sistemas de puntuación subjetiva han sido más sensibles a la desnutrición y, en conjunto, los indicadores antropométricos pueden resultar en una detección temprana del riesgo de mortalidad en esta población. Por otro lado, la inflamación en HD, evaluada por la proteína C reactiva, no solo se relaciona con alteraciones cardiometabólicas, sino que también es uno de los puntos clave en el desarrollo de la desnutrición, exacerbada por el estado de estrés oxidativo, que ha sido identificado en este grupo por el aumento de los niveles séricos de gamma-glutamyl transferase y malondialdehído.
INTRODUCTION

End-stage renal disease (ESRD), as well as hemodialysis (HD), treatment are marked by clinical-nutritional conditions that increase morbidity and mortality and reduce life quality of patients with this chronic disease (1-3). In this sense, hypoalbuminemia, which is also affected by inflammation status and age, is not able to accurately reflect the nutritional state (4). In turn, body mass index (BMI) has been associated with better prognosis of individuals in HD, which is known as “reverse epidemiology” (5-7). This relationship is influenced by characteristics such as age, inflammation and related-comorbidities (8). In addition, subjective global assessment may help predict mortality, when properly applied (9).

On the other hand, the progressive deterioration of renal function leads to physiological dysfunctions such as changes in cellular energy metabolism, protein catabolism, insulin resistance and synthesis of mediators of inflammation and oxidative stress (10-12). Still, the complex inter-relationship among nutritional indicators and inflammatory and oxidative markers remains the object of investigation on the premise to get better prediction of mortality in patients with ESRD in HD (13).

Overall, the objective of this integrative review was to present and discuss the latest scientific literature on the ability of clinical-nutrition indicators, and inflammatory and oxidative stress markers to predict morbidity and mortality in HD individuals.

STUDY CHARACTERISTICS AND SELECTION CRITERIA

A review search was carried out from the databases LILACS, Medline, PubMed, SciELO and BIREME, using the keywords “hemodialysis and mortality”, “chronic renal failure”, “ESRD”, “biochemical markers”, “inflammatory markers”, “oxidative stress markers”, “anthropometric evaluation”, “nutritional status”, “subjective evaluation”, combined with “mortality”. Publications carried out from 2010 to 2016 with HD individuals were included.

From the selected articles, a reverse search was carried out for studies whose titles would be eligible. Subsequently, the abstracts were read to ensure compliance with the inclusion criteria and then each article was entirely read to confirm its eligibility. Cohort studies with adults and elderly individuals in HD treatment were included. Articles that were not published in full or those presented as tutorials, editorials, news, letters or comments, reviews and experimental testing were excluded. In addition, studies of acute renal disease, chronic kidney disease under conservative treatment or treatment with peritoneal dialysis, transplantation and nephrotic syndrome were excluded.

During the initial selection process, 155 articles were found, from which 108 were excluded, as shown by figure 1. Selected papers are related to anthropometric indicators (four studies), subjective global assessment (five studies), oxidative stress markers (two studies), and inflammatory markers (four studies) as predictors of mortality in HD individuals.

Figure 1.
Flowchart showing selected studies for this review (2010-2016).

CLINICAL-NUTRITIONAL PREDICTORS AND MARKERS OF INFLAMMATION AND OXIDATIVE STATE OF THE STUDY

The 15 selected studies used as anthropometric indicators, BMI, waist circumference (WC), skinfold thickness, arm circumference (AC), Mid-arm circumference (MAC), mid-arm muscle circumference (MAMC) lean tissue index (LTI) and fat tissue index (FTI) and total body fat (TBF), assessed by bioelectrical impedance analysis (BIA). Subjective methods to nutritional assessment were: Subjective Global Assessment (SGA), Modified Subjective Global Assessment (mSGA), Objective Score of Nutrition on Dialysis (OSND), International Society of Renal Nutrition and Metabolism (ISRNM), Malnutrition-Infammation Score (MIS) and Geriatric Nutritional Risk Index (GNRI).

Hemoglobin, albumin, calcium, phosphorus, parathyroid hormone (PTH), aspartate aminotransferase (AST), alanine aminotransferase (ALT), alkaline phosphatase, total cholesterol (TC), tri-glycerides (TG), uric acid, urea, creatinine, Kt/V urea (Kt/V), ferritin and transferrin were used as metabolic markers.

The oxidative stress markers used in the studies were plasma concentrations of gamma-glutamyltransferase (GGT), nitric oxide (NO) and malondialdehyde (MDA); while the inflammatory markers were plasma concentrations of C-reactive protein (CRP), interleukin-6 (IL-6), tumor-necrosis factor alpha (TNF-α) and their receptors (TNFR1 and TNFR 2).
The articles were separated in accordance with categories of predictors of mortality in HD as follows: anthropometric indicators, subjective scores, oxidative stress and inflammation markers (Tables I to IV).

ANTHROPOMETRIC INDICATORS ON MORTALITY IN HD INDIVIDUALS

Studies show that protein-energy malnutrition is present in a range of 23% to 76% of individuals in HD (14). Unlike the general population, a higher BMI in these individuals was associated with better survival, fact presented as reverse epidemiology in the literature (15). However, BMI measures did not present differences between lean and fat mass, making it difficult to quantitatively understand which components of body composition are related to survival in HD individuals with ESRD (16). In order to evaluate body compartments, the studies use the Body Composition Monitor (BCM) based on spectroscopic bioimpedance (BIS). Bioimpedance methodologies, the BCM expresses body composition as a three-compartment model, providing overhydration, lean tissue index (LTI), and fat tissue index (FTI), whereby LTI and FTI are the respective tissue compartments, the studies use the Body Composition Monitor (BCM) based on spectroscopic bioimpedance (BIS). Bioimpedance methodologies, the BCM expresses body composition as a three-compartment model, providing overhydration, lean tissue index (LTI), and fat tissue index (FTI), whereby LTI and FTI are the respective tissue masses normalized to height squared. Also, LTI and FTI percentiles (< 10th percentile [low]; 10th-90th percentile [normal]; and > 90th percentile [high]) relative to an age- and sex-matched healthy population are supplied. The three-compartment model of the BCM has been validated against standard reference methods for assessment of fluid status and body composition in dialysis patients. Castelhano et al. (17) have indicated LTI and FTI reference values (10th and 90th percentiles), adjusted for age and sex, in which lean tissue below the 10th percentile was associated with higher mortality in HD (OR: 1.57). Similarly, considering age, sex and diabetes mellitus, higher percentage of lean body mass was associated with better survival (18,19) in HD individuals for the same population.

Moreover, Rosenberger et al. (20) evaluated the relationship between scarcity of lean tissue (expressed as LTI below the 10th percentile) and survival in HD. The possible causes to worse survival (21,22) included malnutrition and inflammation signal (21) as lean mass stocks uremic toxins, in which case, the smaller amount of lean tissue could indicate a higher concentration of uremic toxins in the blood (21,23).

The relation of muscle mass and increased mortality caused by infections in HD individuals is well known, since subjects with ESRD develop an acquired immune deficiency that may be exacerbated in those with low muscle mass and hipoalbuminemia (24). In this sense, Marcelli et al. (16) had found that body composition by multifrequency bioimpedance and LTI and FTI between the 10th and 90th percentiles were associated with improved survival, while the low LTI and FTI, and especially the combination of both, were associated with increased mortality, regardless of BMI.

AC: arm circumference; BMI: body mass index; BSF: bicipital skinfold; CRP: C-reactive protein; FTI: fat tissue indices; HD: hemodialysis; LTI: lean tissue indices; MAC: mid-arm circumference; MAMC: mid-arm muscle circumference; TSF: triceps skinfold; SSF: subscapular skinfold.
Other anthropometric and body composition indicators do not qualify as common practices. TBF and simple anthropometric measures, such as MAC, AC and triceps skinfold thickness (TSF) are generally used (25,26). Stosovic et al. (27) found that the TBF, TSF, AC and MAC were independent predictors of mortality for individuals in HD. The predictive values of all these anthropometric indicators for mortality were similar, except for BMI. When these indicators were altogether tested, the AC was the indicator with the greatest power to predict mortality and showed an average reduction of 8.0% in the proportional mortality risk.

Furthermore, the reduction of muscle mass in this population (28) is associated with hypoalbuminemia and PEM, which indicate inflammatory conditions (29). Su et al. (24) have reported that the decline in lean body mass over time, estimated by MAC and skinfold measurements were associated with higher risk of all specific causes of mortality in HD individuals. These relationships were particularly strong in those with BMI < 25 kg/m².

It is noteworthy that BMI values for individuals in HD are usually higher than for general population, although many of them may present LTI values below percentile 10 (30), suggesting that body composition related to lean tissue is more important than BMI isolated. In addition, interventions to keep lean and fat mass suitable are favorable for survival in population with ESRD. These relationships were particularly strong in those with BMI < 25 kg/m².

**SUBJECTIVE SCORES ON MORTALITY IN HD INDIVIDUALS**

In this sense, SGA is a simple method for assessing the nutritional status in many patients, including those with ESRD. Vogt and Caramori (31) had presented prevalence of malnutrition of 26.3% by SGA, 25.2% for MIS (MIS > 8) and 28.8% by criteria based on ISRNIM, and malnutrition evaluated by SGA and MIS was able to predict mortality in a period of 15.5 ± 5.4 months. The study of Zuijdewiniet et al. (32) highlighted the SGA and MIS, was able to predict mortality in a period of 15.5 ± 5.4 months. Another study has shown that an 1-point increase of SGA and MIS on clinical outcomes and predictors of mortality. As results, these studies show the impact of changes in scores of SGA and MIS on clinical outcomes and mortality risk. Another study has shown that an 1-point increase in SGA, 12 months after dialysis, was independently associated with an increase of 34% in all-cause mortality risk when tested with albumin, CRP, and BMI (33). The same finding was discussed by Chan et al. (34), after adjusting for all variables including age, sex, HD time, serum albumin, body mass index and smoking. In addition, they observed that the SGA, considering mild malnutrition (B) and moderate (C) independently predicts mortality. The study of Beberashvili et al. (35) has found significant associations with hospitalization and mortality in individuals in HD through a comprehensive OSND scoring system. Both variables were significantly correlated with inpatient days and frequency, as well as lean and fat body mass, MIS, blood pressure and IL-6 values (35,36). The results found by Beberashvili et al. (37) indicate that MIS had reliability and good concurrent and predictive validity (37). Even so, these scoring systems should be considered as complementary clinical markers of malnutrition state, while application of MIS and SGA is a simple method for assessing the nutritional status in many patients, including those with ESRD. Vogt

of SGA and MIS could result in early detection of malnutrition compared to metabolic and inflammatory markers, or classic anthropometric indicators (38). Therefore, SGA and MIS may represent good tools for application in clinical practice, as they may contribute to an early identification of malnutrition.

**OXIDATIVE STRESS MARKERS ON MORTALITY IN HD**

The presence of oxidative stress, as well as anthropometric and subjective evaluation, has been related to the increase in morbidity and mortality in cardiac surgical patients, critically ill and renal patients requiring HD (39, 40).

In HD individuals, increased oxidative stress results from an imbalance between pro-oxidant activity and anti-oxidant systems, more intensely, contributing to increased morbidity and mortality (41, 42). Diabetes mellitus, advanced age, inflammation, excess of uremic toxins, bio-incompatibility of dialysis membranes (43) and intravenous iron therapy (44) are the main causes of increased pro-oxidant activity in these individuals (42).

Excess of oxygen reactive species (ROS) can produce cellular damage, interacting with biomolecules (proteins, lipids and nucleic acids) and, thus, have negative effects on tissue function and structure. ROS can react with polyunsaturated fatty acids that produce lipid hydro peroxides. MDA, a linolenic acid product of decomposition of the main final oxidation reactions of polyunsaturated fatty acids, is a useful indicator to evaluate oxidative damage (45, 46). MDA can still interact with DNA and proteins, and can lead to mutagenic and cytotoxic effects and, possibly, is involved in the pathogenesis of various diseases, such as atherosclerosis (47). Low MDA values, which suggest a lower intensity of oxidative stress, are associated with better survival (45).

Rusu et al. (48) observed that the increase in MDA is associated with a higher ratio of albumin corrected calcium (cCA). It is known that elevated cCA is a predictor of mortality, since hypercalcemia and increased ROS can act synergistically in aggravating the severe vascular lesions found in HD individuals. MDA has a high predictive value for the mortality of these individuals and is related to the survival of this population, especially when associated with cardiovascular diseases.

GGT (49), a recognized biomarker for liver disease, was another marker of oxidative stress presented as a predictor of mortality in HD individuals. It is an enzyme with important role in the extra-cellular catabolism of glutathione, a representative intracellular antioxidant (50). GGT-mediated oxidative stress may be involved in the formation of coronary atherosclerotic plaques and endothelial dysfunction (51–53).

In this sense, oxidative stress may play an important role in the pathogenesis of atherosclerosis and cardiovascular risk in ESRD, thus contributing to the increase in mortality. More studies are necessary to identify potential biomarkers in these people. Still, an early evaluation through GGT and MDA may contribute to a better monitoring of oxidative stress presence, which is common among individuals with chronic kidney disease.

**INFLAMMATORY MARKERS ON MORTALITY IN HD INDIVIDUALS**

Inflammation has recently been recognized as an essential component in ESRD in HD, playing a unique role in its pathophysiology and is responsible, in part, by CVD mortality end all other causes (54). Moreover, inflammation is related to the development of PEM and other comorbidities. In fact, the increase in release or activation of pro-inflammatory cytokines such as IL-6 or TNF-α, as well as acute phase protein CRP, may suppress appetite, cause muscle proteolysis and hypoalbuminemia (55). Furthermore, PEM and inflammation contribute independently to hypoalbuminemia and thus increase the risk for mortality in ESRD in HD (56).

Inflammation is often present in individuals in HD, and the use of central venous catheter has been linked to chronic inflammatory state (57). Faria et al. (58) have found that its use as vascular access for HD procedure was independently associated with mortality in patients with high concentrations of CRP and low triglycerides.

In this context, the inflammation as assessed by CRP is present between 30% and 60% of American north and Europeans individuals in dialysis (59). In addition, values of CRP higher than 5 mg/L (60) or 10 mg/L (61, 62) have been positively associated to cardiovascular mortality. Inflammatory markers such as TNF-α and CRP are powerful independent predictors of risk for atherosclerosis, cardiovascular disease and mortality in HD individuals (63). The study of Nakagawa et al. (64) has shown that TNF-α and CRP were positively associated with the causes of cardiovascular mortality, after adjusting for age and sex. When stratified by GNRI, TNF-α and CRP were positively associated with all-cause mortality, only in malnourished individuals. This is supported by the finding of Carlsson et al. (65), concerning the slightly higher values of TNFR 1 and 2 in subjects with malnutrition. However, inflammation can elevate risk of mortality in patients with ESRD in HD by increasing cardiovascular risk and malnutrition.

Thus, the inflammation in individuals in HD, particularly evaluated by the CRP, is not only related to the cardiovascular alterations, including atherosclerosis, but it is also one of the key points in the development of PEM, stimulated by the oxidative stress. This fact can be reversed through a better follow-up of these individuals through PCR, TNF-α, IL-6, identifying the evolution of inflammation and providing better nutritional support, aiming to improve the clinical picture of the individual with ESRD in HD.

**CONCLUSIONS**

In the absence of a gold standard to assess the mortality risk of HD individuals, application of one of the subjective methods together with adiposity and lean mass indicators, and CRP concentration in the clinical-nutritional practice could offer more accurate mortality risk in this population. Although oxidative stress biomarkers in ESRD are important, more studies are necessary to identify a recognized oxidative stress marker as a mortality predictor in HD.
